EXECUTIVE SUMMARY

This Hydrogeological Report: Groundwater Mounding Analysis for Proposed Subsurface Disposal System at Cascade Development in Wayland, MA summarizes the results of hydrogeologic field investigations and two-dimensional groundwater mounding analyses conducted in support of a proposed subsurface disposal system at Cascade Development, Wayland, Massachusetts.

1.0 INTRODUCTION

Geosphere Environmental Management, Inc. (GEOSPHERE) is pleased to submit this Hydrogeological Investigation Report on behalf of Eden Management, Inc., to predict and assess the impacts of a proposed subsurface domestic wastewater disposal system in conjunction with the redevelopment of the former Mahoney Garden Center property located 113 - 119 Boston Post Road, Wayland, Massachusetts. The property is currently occupied by the former buildings of the Garden Center and a separate residential dwelling. A multi-family redevelopment project is proposed.

The proposed disposal system will consist of two leach fields, LF1 and LF2. The design flow for the proposed disposal system is 9,813 gallons per day (gpd) in accordance with Massachusetts Environmental Code Title 5.

This report summarizes the field investigation conducted to collect hydrogeological data in support of a twodimensional groundwater computer model, developed and calibrated for the site.

The hydrogeologic assessment included: an evaluation of subsurface information collected from test pit excavations (percolation rates, depths to mottling and/or groundwater); installation of groundwater monitoring wells and advancement of soil test borings; review of published geologic information pertinent to the site and area; laboratory permeability testing and sieve analysis of selected soil samples from test borings, and establishing an estimated seasonal high groundwater elevation table (ESHGW) for the site.

Once these pertinent hydrogeologic parameters were identified, a 2-dimensional groundwater flow model was developed to predict potential impacts of the proposed subsurface wastewater disposal system (SSDS) on both ground and surface water, as required by Section L of the Wayland Board of Health regulations for septic systems; including the prediction of groundwater mounding heights during estimated seasonal high groundwater (ESHGW) conditions.

2.0 SITE DESCRIPTION

The 6.4 acre site lies south of Boston Post Road, east of the intersection with Pine Brook Road, see **Figure 1**. The site is bisected by Pine Brook, which flows west, toward the Sudbury River. The portion of the property that is subject to this hydrogeologic study abuts Boston Post Road (Route 20) and lies to the north of Pine Brook, see **Figure 2**. The area of the property south of Pine Brook is undeveloped, and will remain so under the Cascade proposal.

The site is comprised of two adjoining lots, Wayland Assessor's Map 30, Lots 70 and 71. The easternmost parcel is a 1.265 acre lot (Map 30, Lot 70) currently occupied by a two-story wood framed private residence and two-story barn. The buildings are located in the northeastern part of the site. The western parcel is a 5.217 acre lot (Map 30, Lot 71) currently occupied by buildings that previously served as the garden center's retail showroom and green houses. Existing utilities at the site include publicly-supplied subsurface water lines, overhead electricity and subsurface natural gas. On-site septic leach fields served the former garden center and residence. An on-site irrigation well served the garden center since 2003.

A multi-family residential development is planned for the site. The redevelopment project proposes disposing of domestic wastewater in two on-site leach fields, LF1 and LF2, to be located in the central-east portion of the site. The two proposed leach fields will encompass approximately 0.46 acre, and are located approximately 120 feet north Pine Brook, as shown on **Figure 3**. Pine Brook is classified as a MA DEP cold water fishery headwater which flows westerly toward the Sudbury River.

3.0 SITE TOPOGRAPHY

The site topography generally slopes gently from east to west. Ground elevations in this area range between 180 and 148 feet NAVD88. Topography across the proposed LF1 and LF2 area also slopes from east to west, with an elevation change of approximately 10 feet, see **Figure 3**.

4.0 SUBSURFACE INVESTIGATION

4.1 Test Pit Excavations

In December 2016, January 2017, and November 2017, Onsite Engineering of Franklin, MA and a representative from the Town of Wayland Board of Health supervised the excavation of a series of 29 exploratory test pits on site. These test pits were performed to obtain subsurface soil and hydrologic information; specifically, to measure soil percolation rates for the SSDS design. The locations of all test pits completed at the site are depicted on **Figure 3**.

The ground elevation, redoximorphic ("mottling") depth and elevation, and total depth of each of the test pits are summarized in **Table 1**. Logs of 23 test pits (OSE-TP-1 through OSE TP-23) are documented on DEP Form 11, which can be found in **Appendix A** of this report. Six test pits (TP-1A, 1B, TP-2 through TP-5) were exploratory and were not formally documented. Percolation test results including date completed, total depth, percolation test results, and permeability test results are documented on DEP Form 12, which can also be found in **Appendix A** of this report.

4.2 Soil Borings and Observation/Monitoring Well Installation

In order to gain more information about the subsurface soils, on November 29, 2017 GEOSPHERE supervised the advancement of nine (9) soil borings at the site. The location of the soil borings and subsequent monitoring wells were reviewed and approved by the Wayland Board of Health. Seven of these soil borings were converted into permanent groundwater monitoring wells. The borings were drilled and monitoring wells were installed by Crawford Drilling Services of Westminster, Massachusetts using direct push/GeoProbe equipment. As a result of difficulty advancing the GeoProbe equipment at B-3, Crawford returned to the site with a hollow stem auger drill rig to complete that borehole and monitoring well. Boring logs can be found in **Appendix B**. The locations of the soil borings and wells completed on site are shown on **Figure 2** and **Figure 3**.

GEOSPHERE's on-site geologist visually characterized soil samples and selected nine representative samples to be submitted for sieve testing (particle size distribution analysis) and hydraulic permeability analysis by GeoTesting Express of Acton, MA. A summary of sample IDs, depths, and permeability test results can be found in **Table 2**. Lab reports for all soil samples submitted for permeability and grain size analysis can be found in **Appendix C**. Refusal in dense silt was encountered at 12 to 22 feet below ground surface (bgs). Locations, ground surface elevations, groundwater elevations, and refusal elevations for each boring are summarized in **Table 3**.

Five of the soil borings were completed as groundwater monitoring wells using 2-inch diameter PVC slotted screen and riser. Monitoring wells MW-1, MW-3, MW-4, MW-5 and MW-7 were installed in test borings B-1, B-3, B-4, B-5 and B-7, respectively.

4.3 Site Stratigraphy and Hydrogeologic Characterization

During monitoring well installation activities, soil samples were collected and visually characterized by a GEOSPHERE geologist. At the completion of the drilling program, boring logs and well installation diagrams were prepared based on the visual soil descriptions. Boring logs can be found in **Appendix B**.

The subsurface materials encountered in the boreholes were described as 7 to 20 ft. of sand and gravel. A layer of very compact, cohesive silt was encountered below the sand and gravel at borings in the eastern portion of the site, at B-1, B-3, B-4, B-5 and B-6. The top of the silt unit was encountered at elevations between 156 and 160 ft. NAV88. Each of the borings was advanced until conditions became too dense for the equipment to advance, referred to here as 'refusal'. The thickness of the silt layer was not penetrated by the GeoProbe at any of the borings. Bedrock was not encountered in any of the borings. The silt unit was not identified at test boring B-2 or B-9, located in the northeastern portion of the site; these borings encountered refusal prior to reaching the elevation (156 ft.) at which silt was encountered at B-1. The homogeneous silt unit encountered in the eastern portion of the site was not encountered at B-7, in the western portion of the site; which met refusal at 146 ft. The dense sandy silt and gravel encountered at the bottom of B-8 at 142.6 ft. was conservatively modeled as the lower transmissivity silt unit observed elsewhere; see Soil Boring Logs in **Appendix B**.

A 2003 well drillers log, completed by TJ Ogden, Inc. when an irrigation well was installed at the garden center, in the area of OSE-TP-14, reports that silt was encountered to a depth of about 20 ft. bgs, and was underlain by bedrock at 20 ft. bgs, see **Appendix B**.

This data was extrapolated to construct a groundwater mounding model (described below) which presumes a dense silt unit of very low transmissivity separates bedrock and the unconsolidated sand & gravel deposit across the site. For a summary of lithology encountered during test borings, see **Table 4**.

5.0 GROUNDWATER FLOW

The depth to groundwater was measured in each of the monitoring wells by GEOSPHERE on December 12, 2017. Groundwater levels were observed to range from 3.2 ft. bgs at MW-6 to 9.50 ft. bgs at MW-3. Water levels were further collected on two additional dates: on March 21, 2018 and April 6, 2018. The highest water levels were observed in April, ranging from 1.65 ft. bgs in MW-4 to 4.30 ft. bgs in MW-3.

Top of casing and ground elevations at monitoring wells were surveyed by Beals and Thomas, Inc. of Southborough, MA in feet relative to North American Vertical Datum of 1988 (NAVD88). Using these elevations, depth to groundwater measurements collected on April 4, 2018 were converted to groundwater elevation data and groundwater contours are plotted on **Figure 4**. As shown on **Figure 4**, groundwater measurements indicate flow in a westerly direction in the overburden aquifer under a relatively uniform hydraulic gradient of 0.028, measured between MW-3 and MW-7 (an elevation change of 14.33 feet over a distance of 520 feet).

6.0 ESTIMATED SEASONAL HIGH GROUNDWATER CONDITIONS

Groundwater table elevations at each of the on-site monitoring wells were measured three times between December 2017 and April 2018 by GEOSPHERE. The depth to groundwater measurements and groundwater elevation calculations were integrated with data from soil borings and test pit observations to construct a two-dimensional, finite difference (MODFLOW) computer model, described in further detail below. Technical details of the groundwater model are included in **Appendix D**.

The model was constructed to predict groundwater elevations during seasonal high water table conditions under the influence of the proposed wastewater discharge. The highest of the three sets of groundwater level elevations, collected in April 2018, was used to calibrate the model to simulate seasonal high groundwater table conditions.

A simulated Estimated Seasonal High Groundwater (ESHGW) Contour Map, **Figure 5** (and **Appendix D**, **Figure 5**) representing the observed ESHGW elevation was produced by the model for the study area. The map depicts a groundwater table that exceeds GEOSPHERE's observed estimated seasonal high groundwater elevations at the area of LF1, near B-4, and along the western model boundary.

7.0 NUMERICAL MODELING USING MODFLOW

A two-dimensional groundwater model was developed on the MODFLOW platform using the groundwater and subsurface data collected at the site. The model was designed to:

- Estimate seasonal high groundwater (ESHGW);
- Predict the effects of the proposed subsurface disposal system on groundwater height (i.e., "90-day mound height") during seasonal high groundwater conditions;
- Evaluate the potential for breakout;
- Estimate flow path direction, and;
- Assess the potential effects of the proposed Cascade SSDS on Pine Brook.

Initially, soil redoximorphic ("mottling") elevations measured in the test pit were used to calibrate the model for ESHGW elevation. However, actual groundwater table data collected in April 2018 were *higher* than the test pit mottling observations. Therefore, the model was re-calibrated to affect the simulated ESHGW elevations to *meet or exceed nearly all of the observed elevations from both sets of data*, see Summary Table of ESHGW Values in **Appendix D**.

This is considered a conservative method of predicting simulated ESHGW conditions for the site. It does not assume an estimated SSDS discharge superimposed over ambient groundwater conditions, but instead integrates field data collected during seasonal high groundwater conditions.

Simulated ESHGW

The calibrated model resulted in simulated ESHGW in the LF1 area near B-4/MW-4 to be 0.99 ft. higher than the measured groundwater table at B-4/MW-4 in April 2018. Simulated ESHGW levels at the along the western boundary of the model are 1 to 5 feet higher than ground surface elevations, as shown in **Figure 5** of **Appendix D**. However, with only information from B-7 for support, insufficient data was available to define that boundary more precisely; the general head boundary values of the model were set to be higher than necessary in the immediate vicinity of the stream. This resulted in a significantly higher modeled groundwater level where the stream exits the western boundary compared with ground surface. Field observations in April 2018 revealed no flooding of this area. This local error in the model does not impact negatively on the

predicted behavior near the proposed infiltration basins or the simulated interaction between the mound and the stream, see **Appendix D**.

Hydraulic Conductivity

As described in Section 4.3, subsurface soils are generally described as: a sand and gravel layer approximately 7-20 feet thick underlain by a silt layer with very low permeability. To re-create this digitally, the model was constructed of two layers that represent the two distinct hydrogeologic zones. The top of Layer 1 was set to the ground surface elevation; the bottom of Layer 1 was interpolated based on the sand and gravel/silt interface observed during drilling activities. The hydraulic conductivity for each layer was based on an averaging of the results of laboratory-derived values from soil sample analyses, see **Table 2.** The hydraulic conductivity (K) of the sand and gravel layer was set to 90 ft/day, which is conservative when compared with laboratory values, see **Table 2.** The K of the silt layer was set to 1 x 10⁻³ ft/day. As a result, of the silt layer's low conductivity, the model acts as a one-layer, two-dimensional model.

Groundwater Mounding Simulation

Following calibration under steady state conditions, a transient simulation was executed to model effects from infiltration of a 7,850 gallons per day (gpd) (1,049 ft³/day) of domestic wastewater distributed proportionately between the two leach fields. The simulation modeled infiltration over a continuous 90 day period to predict the mounding height during maximum monthly flow conditions. Maximum monthly flow is defined as 80% of the design flow (9,813 gpd) based on the Title 5 calculations, in accordance with Massachusetts Department of Environmental Protection (Mass DEP) guidance.

The mounding simulation resulted in a maximum mound height of 0.29 feet located near the center of LF1, near B-4; see **Figure 6** (and Figure 6 in **Appendix D**). Model results were then superimposed over the ESHGW surface to determine the mound elevation under ESHGW conditions. The simulated mound elevation exceeded the existing ground surface elevation in some areas within leaching field LF1 by less than one foot. The breakout area predicted at LF1 near MW-4 is also the area where the calibrated ESHGW exceeded the observed groundwater level by approximately 1 foot, indicating that the model overestimates groundwater elevations in that region of the site. The thickness of the mound height exceeding ground surface elevation, therefore, is conservatively predicted to be no greater than one foot, see **Figure 5**, **Figure 6** and **Appendix D**. **Figure 7** illustrates the depth from ground surface to the predicted infiltration mound.

The conservative model also predicts mound breakthrough at discrete locations southwest of the leach fields along the Pine Brook drain cells of the model. Breakthrough of less than 0.1 ft. (1.5 inches) is predicted by the model; see **Figure 6** and **Appendix D**.

In both cases we believe the conservative ESHGW calibration is generating higher predicted groundwater elevations than we expect will occur.

Mass Balance Evaluation

The groundwater model was used to predict Mass Balance effects from the proposed SSDS. To assess the changes in ambient groundwater flow in the vicinity of the leach fields, a water budget was calculated for a (rectangular) zone which occupies the majority of the site area northeast of and including Pine Brook (see **Figure 6** and **Appendix D**). Mass balance predictions were calculated under both ESHGW and ESHGW + proposed infiltration scenarios, summarized in the **Table** below.

According to the model, the simulated mound from the proposed SSDS infiltration of 7,850 gpd (1,049 ft³/day) would divert a small percentage of ambient groundwater flow from entering the polygon from the north and east. Groundwater flow comes primarily (84%) from the eastern boundary; due to the predicted effects of mounding, ambient groundwater flow from the east into the polygon is expected to be reduced by 2% (240 ft³/day). The flow regime from the north, estimated at 1,899 ft³/day during ESHGW, is predicted

to be about 13% of total inflow into the model. Due to the diversion from the mound, flow from the north is predicted to be reduced to about $1,658 \text{ ft}^3/\text{day} - \text{a } 14\%$ decrease

Description		ESHGW		90	day w/ infiltration	on	Difference
	Inflow	Outflow	Net (ft³/day)	Inflow	Outflow	Net	Relative
						(ft³/day)	
West		11691	(11,691)		11,823	(11,823)	1%
East	11,874	370	11,504	11,634	404	11,230	-2%
North	1,899	37	1,862	683	64	1,594	-14%
South	333	930	(597)	160	945	(609)	2%
Infiltration				1,049		1,049	n/a
Stream		1,079	(1,079)		1,440	(1,440)	33%

The impact from the proposed infiltration at the SSDSs to fluxes across the southern and western zone boundaries (2% and 1%, respectively of inflow at ESHGW) is predicted to be negligible - a slight increase in outflow (15 ft³/day at the southern boundary and 132 ft³/day at the western boundary) is predicted by the model.

The influence of the mound is predicted to divert some ambient groundwater flow (2%) from the east around the mound to the south, which inhibits the infiltrated volume from the SSDS from reaching the stream to the south of the leach fields.

The model the volume of water discharged into the stream is predicted to increase by 33% from the 1,079 ft³/day predicted under ESHGW conditions to 1,440 ft³/day with the addition of the proposed SSDS infiltration under Title 5 rules.

The increase in the discharge to the stream can be attributed to modeled increase in the hydraulic heads between the leaching fields and the stream due to the infiltration.

For a generalized understanding of hydrodynamics at the site, a particle tracking exercise was performed by applying MODPATH to the model to evaluate the system flow paths and potential interaction with Pine Brook under steady state conditions with constant infiltration at a rate of 7,850 gpd. The output of the model is depicted in **Figure 6** and in **Appendix D**, illustrating most particles passing through the system to the western margin of the model.

8.0 SUMMARY OF FINDINGS

- As shown in **Figure 6**, the simulated groundwater mound beneath leach field LF1 reached a maximum height of 0.29 feet. The simulated groundwater mound was superimposed on top of the ESHGW elevation in **Figure 8** showing the resultant, simulated groundwater elevations at the site under ESHGW conditions and maximum monthly infiltration.
- Areas where the groundwater table is modeled to exceed existing ground surface elevation under ESHGW conditions are shown in **Figure 7**. The areas in light blue on this plan are categorized distinctly: a) within the LF1 area, where ambient groundwater is shallow, the mound is at its peak, resulting in simulated breakout of less than one foot in this area of the site; and, b) little hydrogeologic information is available to define groundwater table conditions in the area where Pine Brook intercepts the general head boundary at the western margin of the model. During calibration, this resulted in the model predicting groundwater elevations higher than observed in the field. Field observations in April 2018 revealed no flooding of these areas. This erroneous artifact carried through the mounding simulation. This local error in the model does not impact the behavior near the proposed infiltration basins or the simulated interaction between the mound and the stream. Due to the characteristics of the model's ESHGW calibration in comparison to the observed ESHGW we believe the breakout results are unique to the model.
- Given the conservative nature in which the simulated ESHGW was estimated, and the fact that the hydraulic conductivity parameters are also conservative estimates, the potential breakout conditions shown in **Figures 6 and 7** represent model only worst-case scenarios that are not likely to manifest.
- Figure 7 depicts the simulated groundwater mound after 90 days of continuous discharge of 7,850 gpd at LF1 and LF2. Ambient groundwater at the site is shallow, ranging from 1.65 to 4.30 ft. bgs during seasonal high water observed in April 2018. Using Title 5 maximum monthly flows (80% of design flows) the top of the groundwater mound breaks out at a small area at LF1, with simulated groundwater mound elevation less than 1 ft. above ground surface. Elsewhere on the area of the site proposed for development, the simulated mound elevation was predicted 2 to 10 ft. below current ground surface elevations during ESHGW. Adequate separation (minimum 4 ft.) between the groundwater mound and ground surface elevations can be achieved through surface re-grading and/or filling in all areas where the simulated mound is less than 4 ft. bgs.
- Groundwater particle flow paths for were simulated under steady state conditions with constant infiltration of 7,850 gpd. **Figure 8** depicts resulting groundwater table elevations from the SSDS mound effect, illustrating that groundwater discharge from the site is weighted to the western boundary of the model.

Estimated average linear velocity through the sand and gravel aquifer is 10.6 ft/day to 17.6 ft/day. This yields a travel time from the Cascade SSDS to the Pine Brook of 6.8 to 11.3 days. Note that the model flow path exercise predicts that most of the water from the area of the SSDS mound will not discharge at the drain cells of Pine Brook, but exit the model at its western boundary, see **Figure 6** in **Appendix D** and **Figure 8**.

9.0 CONCLUSIONS

The conservative MODFLOW groundwater flow model simulation predicts that the modeled subsurface discharge of 7,850 gpd into leach fields LF1 and LF2 results in a maximum groundwater mounding effect of 0.29 ft. during ESHGW periods. Due to the shallow ambient groundwater table conditions at the site, the two-dimensional model predicted groundwater would break-out at ground surface in the area of LF1. Minimum separation between predicted groundwater mounding and ground surface elevation can be achieved through grading any areas where the predicted groundwater mound is less than 4 feet bgs, as depicted on **Figure 7**.

The conservatively-simulated maximum mound effect at the boundary of Pine Brook is less than 0.1 ft. (1.2 inches) at ESHGW. GEOSPHERE has previously worked on projects where MADEP has approved groundwater discharges creating up to 6 inches of mound effect on nearby surface water bodies. The modeled discharge effects are not considered to pose deleterious effects on streamflow or biota.

Furthermore Mass DEP has indicated temperature effects from sanitary subsurface discharges into conventional septic systems are also not expected to be deleterious, as they will be ameliorated within the leach field, located a distance of over 100 feet from Pine Brook. Temperatures consistent with ambient groundwater temperatures are expected to prevail upon discharges into the aquifer surrounding the leach fields.

Form 11 - Soil Suitability Assessment for On-Site Sewage Disposal

Note: In accordance with 310 CMR 15.018(2) this form must be submitted to the approving authority within 60 days of the date of field testing, and to the designer and the property owner with Percolation Test Form 12.

Use this sheet for field diagrams:

See Attached Plans

Commonwealth of Massachusetts City/Town of Wayland Percolation Test Form 12

Important: When filling out forms on the computer, use only the tab key to move your cursor - do not use the return

Percolation test results must be submitted with the Soil Suitability Assessment for On-site Sewage Disposal. DEP has provided this form for use by local Boards of Health. Other forms may be used, but the information must be substantially the same as that provided here. Before using this form, check with the local Board of Health to determine the form they use.

City/Town of Wayland, Massachusetts

Form 11 - Soil Suitability Assessment for On-Site Sewage Disposal

Note: In accordance with 310 CMR 15.018(2) this form must be submitted to the approving authority within 60 days of the date of field testing, and to the designer and the property owner with Percolation Test Form 12.

Use this sheet for field diagrams:

See Attached Plans

Commonwealth of Massachusetts City/Town of Wayland Percolation Test Form 12

Important: When filling out forms on the computer, use only the tab key to move your cursor - do not use the return

Percolation test results must be submitted with the Soil Suitability Assessment for On-site Sewage Disposal. DEP has provided this form for use by local Boards of Health. Other forms may be used, but the information must be substantially the same as that provided here. Before using this form, check with the local Board of Health to determine the form they use.

Groundwater Model Summary Report J. Matthew Davis & Associates, LLC

ADDENDUM TO:

HYDROGEOLOGICAL REPORT: 113-119 Boston Post Road in Wayland Massachusetts Wayland, MA.

J. Matthew Davis & Associates, LLC 2 Maple St Durham, NH

Submitted to:

Geosphere Environmental Management, Inc. Exeter, NH

June 2018

Introduction

This report summarizes the groundwater model development, calibration, and simulation results for proposed leachfields at 113-119 Boston Post Road in Wayland Massachusetts (the "Site"). The primary purposes of the groundwater model are to:

- Synthesize hydrogeologic data available for the Site. These data were provided by Geosphere Environmental Management, Inc (GEOSPHERE) and obtained from Mass GIS.
- Using the data and standard groundwater model techniques, provide the following:
 - Estimated Seasonal High Ground Water (ESHGW)
 - Simulated 90-day mound height due to infiltration in leachfields superimposed on ESHGW.
 - Assessment of 90-day mound height relative to current ground surface elevations, and
 - Assessment of potential impact of leachfield operation on the nearby surface water stream.

DATA SYNTHESIS

The following data sets were utilized in the development of the groundwater model:

- Surface elevations from the 2010 FEMA LiDAR survey (tile 19_03064692) were obtained from the Mass GIS "Oliver" tool, imported into GIS and converted to feet. The ground surface elevations obtained are consistent with surface elevations provided by GEOSPHERE.
- Lithologic observations from 9 boreholes, including bottom of sand and gravel unit (top of Silt Layer) and permeability tests from a subset of 6 boreholes.

- ESHGW estimates from Test Pits (soil mottling) and April 2018 groundwater elevations from 6 Monitoring Wells.
- Surface water location and elevations provided as both GIS shapefiles (locations) and tabulated survey elevations (water surface elevations).
- Contours of observed groundwater elevations.

MODEL DEVELOPMENT

To meet the stated objectives, a MODFLOW model was developed using Groundwater Vistas (version 5.51). The overall model set up is illustrated in Figure 1. The finite difference grid has an overall 6 foot spacing of rows and columns. In the vicinity of the leachfields, the row and column spacings are reduced to approximately 3 feet by 3 feet. The overall model grid size is 155 rows by 217 columns. Two model layers were initially set up – one representing the overlying sand and gravel and the lower representing a low conductivity silt layer.

Based on groundwater observations, the flow is generally east to west and the surface water feature running through the site is expected to be hydraulically connected to the groundwater. For the purposes of this analysis the stream is expected to serve primary as a sink and is modeled using the Drain Package. Heads in the drain cells were set by piecewise linear interpolation based on surveyed water surface elevations. The drain boundary cells are assumed to be in good hydraulic connection with the aquifer and have conductances on the order of a few hundred feet-squared per day.

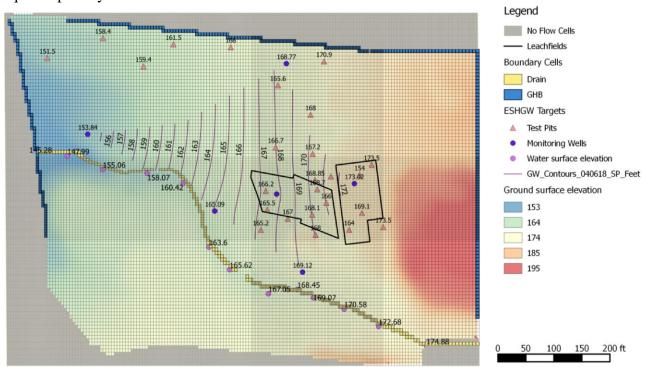

Figure 1. Overview of groundwater model setup.

Because of the limited amount of information available, the relatively limited model objectives, and the appearance of significant east-to-west groundwater flow through the site, the ambient gradient was established using the General Head Boundary (GHB) package along the eastern, northern, and western boundaries of the site. Heads along the boundaries were assigned to mimic

the observed natural gradient. While use of such a boundary condition has the potential to bias the model results, as shown below, the boundary appears to have a negligible impact on the mounding calculations.

The top of Layer 1 is set to the ground surface elevation, as determined by LIDAR, and the bottom is interpolated from 9 borehole observations of the bottom of the sand and gravel deposit (Figure 2). In the western portion of the model, the bottom of Layer 1 was manually reduced to facilitate model convergence in the vicinity of the downstream boundaries. The lower elevation of the bottom of Layer 1 in the vicinity of B7 is not expected to impact the simulation results in vicinity of the proposed leachfields.

Hydraulic conductivity of Layer 1 was set to 90 ft/day, as recommended by GEOSPHERE based on permeability test data.

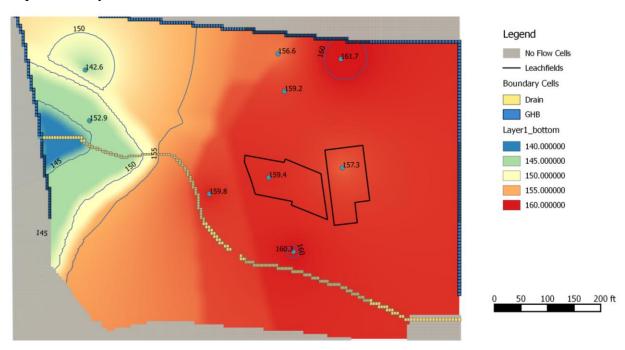

Figure 2. Bottom of Layer 1 interpolated from borehole observations. Adjusted in vicinity of B-7 to facilitate model convergence.

MODEL CALIBRATION

A steady state groundwater model was developed to simulate the estimated seasonal high ground water (ESHGW) elevations. Initially, the calibration targets were the ESHGW ("mottling") elevations observed in the test pits (coded as Group 1 targets). The test pit mottling observations were later augmented with actual seasonal high ground water elevations measured in April 2018 at 6 of the monitoring wells. The observed groundwater levels were added to the list of targets and coded as Group 2. Trial-and-error calibration was conducted until most (4 out of 6) of the simulated groundwater level observations were higher than the observed values.

Surface water elevation data used for Pine Brook was surveyed by Beals & Thomas as part of site plan development activities. In order to match heads with the April 2018 groundwater elevation at MW-6, it was necessary to raise the heads in the DRN cells (which model Pine Brook) by 0.5 feet to simulate surface water elevations that would correspond during periods of ESHGW.

The results of the calibration are shown in Figure 3. It should be noted that the objective of the calibration is to obtain a simulated ESHGW that exceeds most of the observed values, as opposed to most calibration efforts that look to obtain an unbiased (mean zero) set of residuals. As illustrated in Figure 3, the observed groundwater elevations tend to be higher than the ESHGW inferred from the Test Pits.

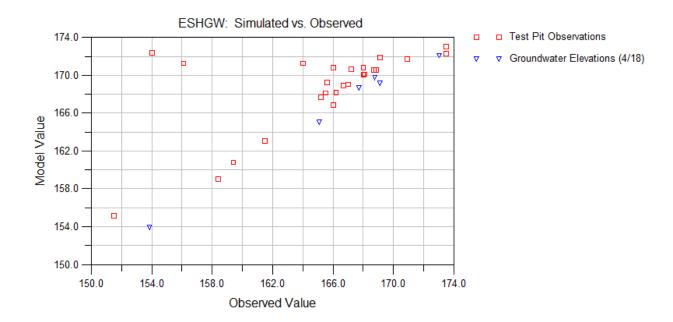

Figure 3. Comparison of simulated ESHGW surface with observations.

It was found that the general head boundary along the perimeter of the model was sufficient to match the heads and ambient recharge is not necessary to simulate the ESHGW surface. As shown in the east-west cross section in Figure 4, the geometry of the boundaries imparts a concave water table surface, as expected in an unconfined aquifer subjected to recharge. This concavity results in an overestimation of the head at B-4/MW (Infiltration Area 1), with a simulated head 0.99 higher than the observed head. Because of the already shallow water table condition, this model error results in the calibrated ESHGW having some heads slightly higher than the ground surface in Infiltration Area 1 under seasonal high conditions (see Figure 5 to the northeast of B-4/MW), which were not observed in the field. While these are artifacts of the model, the seasonal high water table in this area is very shallow. Another artifact of the GHB boundary is illustrated in Figure 5 along with western edge of the model where the GHB boundary allows for groundwater to exit the model out of the western boundary. Detailed field measured groundwater levels were not available along that boundary and the GHB boundary head values were set to be higher in the immediate vicinity of the stream than field observations have borne out. This resulted in the model generating an erroneous over-prediction of groundwater levels where the stream exits the western boundary. This local error in the model does not impact the behavior near the infiltration basins or the simulated interaction between the mound and the stream.

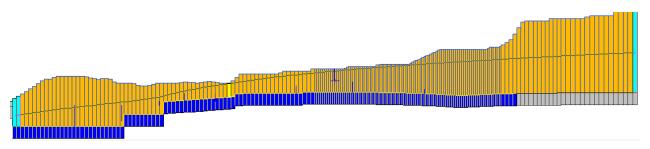

Figure 4. East-west cross section through MW4. Orange cells are Layer 1; dark blue = Layer 2; cyan = GHB; yellow = DRN; gray = No flow. Line of cross section shown in Figure 5.

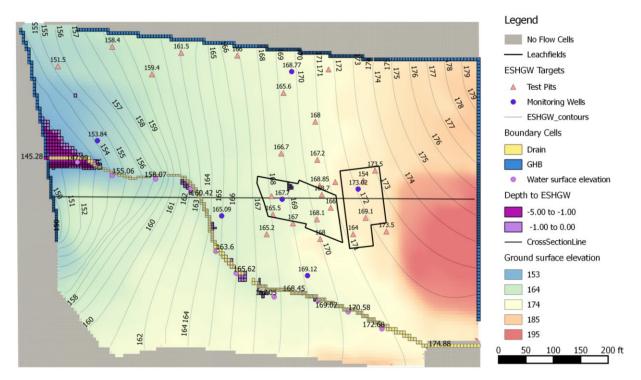

Figure 5. Calibrated ESHGW conditions.

Transient Simulations

To simulate the effects of infiltration in Septic Areas 1 and 2, the steady-state model calibrated to ESHGW was converted into a transient simulation with infiltration applied using the MODFLOW Recharge Package (Table 1). Based on the Title 5 guidance, the model was executed using a maximum monthly flow volume of 7,850, gpd, which is 80% of the design flow 9,813 gpd. The transient simulation has one stress period of 90-day duration, 20 time steps, and a time-step multiplier of 1.2. The initial heads were set to the calibrated ESHGW heads and mound height was computed as the change in head over the 90-day simulation.

Table 1. Infiltration basins, areas, and rates.

Description	Area [Square Feet]	Infiltration [gpd]	Recharge [ft/day]
Septic Area 1	10,304	4,674	0.061
Septic Area 2	8,696	3,176	0.049

Results of the mounding simulation (Figure 6) show a maximum mound height contour of 0.25 feet enclosing the maximum mound height of 0.29 feet. As with the ESHGW simulation, the 90-day simulation of infiltration results in some heads exceeding the ground surface elevation (so-called flooded cells). As shown in Figure 6, when heads in the vicinity of the Septic Areas are higher than the ground surface, they are less than 1 foot. As noted above, the ESHGW simulation exhibits flooded cells in the vicinity of MW-4 and the calibrated ESHGW at B-4/MW is 0.99 feet higher than measured in the field. Therefore, these flooded cells are largely a reflection of the model misfit near B-4/MW.

To assess the changes in flows in the vicinity of the infiltration basins, a Zone Budget was calculated for the rectangular region shown in Figure 6. Analysis of the mass balance illustrates the effect of the boundary condition on the model (Table 2). Without infiltration, the groundwater flow in the steady-state ESHGW model is primarily from east to west with some inflow from the north and a net outflow of 1,079 cubic feet per day to the stream. Under stressed conditions, the flow rates after 90 days approach steady state conditions and show that stream discharge increases by about a third to 1,440 gpd, represents about 34% of the infiltrated water. The mounding from the infiltration results in decreased ambient flow from the east, reducing flow into the polygon from that direction by 2%. Flows from the north are small compared to the east-to-west flow and are decreased by 14%, as groundwater will be diverted around the mound. It is important to note that while the discharge to the stream within the Mass Balance Polygon increases by approximately 360 cubic feet per day (cfd), this increase flow is not necessarily originating from the Septic Areas. As the mounding raises the heads in the vicinity, the increase in heads to the south of the infiltration areas will result in an increase in the discharge to the stream, even though the water is not originating from the infiltration areas.

Table 2. Comparison of fluxes through rectangular region shown in Figure 6.

	ESHGW			90 day w/ infiltration			Difference
Description	Inflow	Outflow	Net (cfd]	Inflow	Outflow	Net (cfd)	Relative
West	-	11,691	(11,691)	-	11,823	(11,823)	1.13%
East	11,874	370	11,504	11,634	404	11,230	-2.38%
North	1,899	37	1,862	1,658	64	1,594	-14.39%
South	333	930	(597)	336	945	(609)	2.01%
Infiltration			-	1,049		1,049	n/a
Stream	-	1,079	(1,079)	-	1,440	(1,440)	33.46%

Particle tracking was performed with MODPATH on a steady state model with constant infiltration. Because the simulated flow is primarily in Layer 1 and that is the layer with the boundary conditions, it is not possible to determine the parcels of water leaving the model that originate as infiltration. To do so would require a multi-layer model with more detailed hydrogeologic information and the use of the solute transport equations using a model such as MT3D-MS. However, to illustrate the flow paths and potential interaction with the stream, it is possible to allow traced particles to exit the model using a 'weak sink' option in MODPATH. For the simulations presented here, the "weak sink strength" parameter was set to 0.25, meaning that particles will exit the cell when 25% or more of the flow into the cell discharges to the

boundary cell. As shown in Figure 6, many particles pass through cells in which less than 25% of the water discharges to the stream and these particles continue to the GHB cells along the western margin of the model.

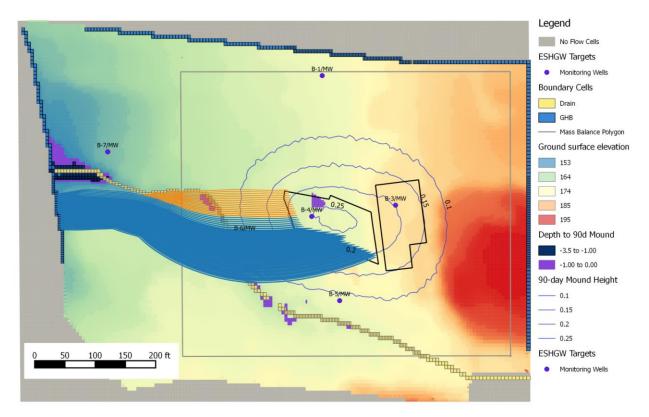

Figure 6. Results of 90-day transient simulation with infiltration and steady state particle tracking. Particle traces are colored based on the type of boundary cell to which they exit (orange = DRN; blue = GHB).
